RELATIVISTIC THEORY OF CALCULATION OF E1 TRANSITION AMPLITUDES, AND GAUGE INVARIANCE PRINCIPLE

The combined relativistic energy approach and relativistic many-body perturbation theory with the zeroth order Dirac-Kohn-Sham one-particle approximation are used for estimating the energies and the E1 radiative transitions amplitudes (oscillator strengths) for the low-excited states of the francium. The comparison with available theoretical and experimental (compiled) data is performed. The important point is linked with an accurate accounting for the complex exchange-correlation (polarization) effect contributions and using the optimized one-quasiparticle representation in the relativistic many-body perturbation theory zeroth order that significantly provides a physically reasonable agreement between theory and precise experiment.

1. Introduction

The development of new directions in the field of laser, atomic physics, quantum electronics, etc., such as pulsed heating methods in research on controlled thermonuclear fusion, new laser schemes in VUV, X-ray spectral regions, astrophysical studies, etc., necessitates the solution of new classes of problems of atomic and laser physics at a fundamentally new level of theoretical consistency and accuracy. Significant progress in the development of experimental research methods, in particular, a significant increase in the intensity and quality of laser radiation, the use of accelerators, heavy ion colliders, sources of synchrotron radiation and, as a result, the possibility of studying more and more energy processes, stimulates the development of new theoretical methods in the theory of heavy atoms calculation of their characteristics, in particular, radiation and autoionization ones [1–10].

However, a study of the spectral characteristics of heavy atoms and ions in the Rydberg states has to be more complicated as it requires a necessary accounting for the relativistic, exchange-correlations effects and possibly the QED corrections for superheavy atomic systems. The simultaneous correct accounting of relativistic, quantum electrodynamic (QED), and many-particle correlation effects is essential [1–10]. The results of calculating the characteristics of atomic processes based on modern theoretical methods often differ several times.

The difference in the values of the transition amplitudes, the oscillator strengths, and the radiation widths for heavy atoms using various expressions for the photon propagator reaches 5–30% (we are essentially talking about the non-fulfillment of the principle of gauge invariance when calculating physical quantities) [11–18]. From the point of view of applications for the majority of the most important atomic systems, there is very often partially or completely missing information on their energy, radiation or/and autoionization characteristics (heavy atoms, atoms of alkaline-earth elements, lanthanides and actinides).

In this paper the combined relativistic energy approach and relativistic many-body perturbation theory with the zeroth order Dirac-Kohn-Sham 1-particle approximation [2,19] are used for are used for estimating the energies and the E1 radiative transitions amplitudes (oscillator strengths) for some low-excited states of the francium atom and studying an effect of the gauge invariance on the transition amplitude values for heavy atoms on example of the francium.
2. The theoretical method

In Refs. [2,18-22] the fundamentals of the relativistic many-body PT formalism have been in detail presented, so further we are limited only by the novel elements. Let us remind that the majority of complex atomic systems possess a dense energy spectrum of interacting states. In Refs. [10-12] there is realized a field procedure for calculating the energy shifts $\Delta E$ of degenerate states, which is connected with the secular matrix $M$ diagonalization. The whole calculation of the energies and decay probabilities of a non-degenerate excited state is reduced to the calculation and diagonalization of the $M$. The complex secular matrix $M$ is represented in the form:

$$M = M^{(0)} + M^{(1)} + M^{(2)} + M^{(3)},$$  \hspace{1cm} (1)

where $M^{(0)}$ is the contribution of the vacuum diagrams of all order of PT, and $M^{(1)}, M^{(2)}, M^{(3)}$ are the ones-, two- and three-QP diagrams respectively. The diagonal terms of $M^{(1)}$ can be presented as a sum of the independent 1QP contributions. The optimized 1-QP representation is the best one to determine the zeroth approximation. In the relativistic energy approach, which has received a great application during solving numerous problems of atomic, molecular and nuclear physics (e.g., see Refs. [21-27]), the imaginary part of electron energy shift of an atom is directly connected with the radiation decay possibility (transition probability). An approach, using the Gell-Mann formula with the QED scattering matrix, is connected with the secular matrix $M$. Naturally, the physical values should not depend on the calibration of the photonic propagator. In general form, it can be written as

$$D = D_T + C \cdot D_L,$$  

$$D_T = \frac{\delta \mu \nu}{k^2 - k^2},$$  

$$D_L = \frac{k \mu k}{k^2 - k^2}$$  \hspace{1cm} (5)

where the term $D_L$ is corresponding to exchange by transverse photons, $D_L$ — longitudinal ones, $C$ is the gauge constant. Contribution of the main exchange-correlation (the second and higher orders of the atomic perturbation theory or fourth etc of the QED perturbation theory) diagrams to imaginary part of an electron energy shift looks like [11]:

$$\text{Im} E_{mn}(\alpha - s | A_s) = -C \frac{e^2}{4\pi} \int \int \int \int \int \int \int \int dx dy dz dr dr dr dr dr dr$$  

$$\sum \left\{ \frac{1}{\omega_{mn} + \omega_{ss}} + \frac{1}{\omega_{mn} - \omega_{ss}} \right\} \Psi^\dagger(r_i) \Psi^\dagger(r_2) \Psi^\dagger(r_3) \Psi^\dagger(r_4) \cdot$$

$$\cdot \Psi^\dagger(r_i) \left( 1 - \alpha \gamma_5 \right) / r_i \cdot \left\{ \left[ (\alpha, \gamma_5) - (\alpha, n_s) \right] (\alpha, n_s) \right\} / r_s \cdot$$

$$\cdot \sin[\omega_{ss} (r_s + r_s) + \omega_{ss} \cdot \cos[\omega_{ss} (r_s + r_s)] / (1 + (\alpha, n_s))] \right\} \Psi^\dagger(r_i) \Psi^\dagger(r_2) \Psi^\dagger(r_3) \Psi^\dagger(r_4)$$  \hspace{1cm} (6)

Expression (6) can be represented as an sum:

$$\sum \langle am | W_j | s \rangle \langle s | W_2 | m_0 \rangle / (\omega_{m_0} \pm \omega_{ss})$$  \hspace{1cm} (7)

with (4) different operator combinations $W_j$, $W_2$. The sum over $n$ can be calculated by the
method of differential equations. The index \( m \) numbers a finite number of states occupied in the core and the state of the real continuum. The continuum-related part describes the vacuum polarization of the electron field and leads to divergent integrals in the non-renormalizable theory. Its contribution to the main contribution has an additional order of smallness (\( aZ^2 \)). The minimization of the density functional \( \text{Im}dE \) leads to the integral differential equation for the \( \mathcal{r}_c \) that can be numerically solved. This step allows to determine the optimization parameter \( b \). In Ref. [11] the authors elaborated a simplified computational procedure.

The contribution of the main exchange-correlation (the second and higher orders of the atomic perturbation theory or fourth etc ones of the QED perturbation theory) to imaginary part of an electron energy shift is determined by the polarization of an atomic core, which is related to the electronic core density \( \rho_c \). The expression (6) can be represented as a functional of the density \( \rho_c \).

Under calculating the matrix elements (2) one should use the expansion for potential \( \sin|w| r_{12}/r_{12} \) on spherical functions as follows [10,11]:

\[
\frac{\sin|w|}{r_{12}} = \frac{\pi}{2(2\pi)^2} \sum_{l=0}^{\infty} \frac{(-1)^l}{l} \frac{\mathcal{J}_l(r_{12})}{\mathcal{Y}_l^2} \frac{\mathcal{J}_l(r_{12})}{\mathcal{Y}_l^2} (\cos r_{12})^l \tag{8}
\]

where \( J \) is the Bessel function of first kind and \( l=2l+1 \). Substitution of the expansion (5) to matrix element of interaction gives as follows [14]:

\[
V_{1234}^{\alpha} = \left[ \sum_{\mathcal{m}} -1 \right] \left[ \frac{j_i j_f}{m_i} \frac{j_i j_f}{m_i} \frac{\lambda}{\mu} \right] \times \text{Im}Q_{\alpha}^{\text{out}}(1234) + Q_{\alpha}^{\text{Breit}}(1234) \tag{9}
\]

where \( j_i \) is the total single electron momentums, \( m_i \)- the projections; \( Q_{\alpha}^{\text{out}} \) is the Coulomb part of interaction, \( Q_{\alpha}^{\text{Breit}} \) - the Breit part. Their detailed definitions are presented in Refs. [10-11,18,19]. The relativistic wave functions are calculated by solution of the Dirac equation with the potential, which includes the “outer electron-ionic core” potential and exchange-polarization potential [20]. In fact, we realize the procedure of optimization of relativistic orbitals base. The main idea is based on using ab initio optimization procedure, which is reduced to minimization of the gauge dependent multielectron contribution \( \text{Im}dE_{\text{inv}} \) of the lowest QED PT corrections to the radiation widths of atomic levels. According to [11,18], “in the fourth order of QED PT (the second order of the atomic PT) there appear the diagrams, whose contribution to the \( \text{Im}dE_{\text{inv}} \) accounts for correlation effects and this contribution is determined by the electromagnetic potential gauge (the gauge dependent contribution)”. The accurate procedure for minimization of the functional \( \text{Im}dE_{\text{inv}} \) leads to the Dirac-Kohn-Sham-like equations for the electron density that are numerically solved by the Runge-Cutta standard method It is very important to know that the regular realization of the total scheme allows to get an optimal set of the 1QP functions and more correct results in comparison with so called simplified one, which has been used in Refs. [11-13] and reduced to the functional minimization using the variation of the correlation potential parameter \( b \). Other details can be found in Refs. [11,18,19,29].

The adequate, precise computation of radiative parameters of the heavy Rydberg alkali-metal atoms within relativistic perturbation theory requires an accurate accounting for the multielectron exchange-correlation effects (including polarization and screening effects, a continuum pressure etc). These effects within our approach are treated as the effects of the perturbation theory second and higher orders. Using the standard Feynman diagrammatic technique one should consider two kinds of diagrams (the polarization and ladder ones), which describe the polarization and screening exchange-correlation effects. The detailed description of the polarization diagrams and the corresponding analytical expressions for matrix elements of the polarization interelectron interaction (through the polarizable core of an alkali atom) potential is presented in Refs. [2,18,19,29].

An effective approach to accounting for the polarization diagrams contributions is in adding the effective two-quasiparticle polarizable operator into the perturbation theory first order matrix elements. In Ref. [10] the corresponding non-relativistic polarization functional has been derived. More correct relativistic expression has
been presented in the Refs. [2,18] and used in our theory. The corresponding two-quasiparticle polarization potential looks as follows: (10a)

\[ V_{pol}(r_1r_2) = X \left\{ \int \frac{dr \rho_c^{(0)}(r)^3 \theta(r)}{|r_1 - r|} - \int \frac{dr \rho_c^{(0)}(r)^3 \theta(r)}{|r - r_2|} \right\} \]

\[ - \int \frac{dr \rho_c^{(0)}(r)^3 \theta(r)}{|r_1 - r|} \int \frac{dr \rho_c^{(0)}(r)^3 \theta(r)}{|r - r_2|} \left\{ \left( \rho_c^{(0)}(r) \right)^3 \right\} \]

(10a)

\[ \langle \rho_c^{(0)}(r)^3 \rangle = \int dr \rho_c^{(0)}(r)^3 \theta(r), \quad (10b) \]

\[ \theta(r) = \left\{ 1 + \left[ 3 \pi^2 \cdot \rho_c^{(0)}(r) \right]^{2/3} / c^2 \right\}^{1/2}, \quad (10c) \]

where \( \rho_c^{(0)} \) is the core electron density (without account for the quasiparticle), \( X \) is numerical coefficient, \( c \) is the light velocity. The contribution of the ladder diagrams (these diagrams describe the immediate interparticle interaction) is summarized by a modification of the perturbation theory zeroth approximation mean-field central potential (look [2,18]), which includes the screening (anti-screening) of the core potential of each particle by the two others. All computing was performed with using the modified PC code “Superatom-ISAN” (version 93).

3. Results and conclusion

We applied the above described approach to compute the oscillator strengths (reduced dipole matrix elements) for a number of transitions in spectra of the heavy alkali atoms and corresponding ions.

As an illustration we present below the data for francium. In Table 1 there are listed the theoretical reduced dipole matrix elements for a number of transitions, computed within: i) relativistic Hartree-Fock (RHF) method [6], ii) the empirical relativistic model potential method (ERMP) [7], iii) the relativistic single-double (SD) method in which single and double excitations of the Dirac-Hartree-Fock (DHF) wave function are included to all orders of perturbation theory [8] and iv) our data.

Let us note that the precise experimental data for the francium \( 7p_{1/2,3/2} - 7s \) transition are as follows: \( 7p_{1/2} - 7s = 4.277 \) and \( 7p_{3/2} - 7s = 5.898 \) [8]. The important features of the approach used are using the optimized one-particle representation and an effective taking into account the exchange-correlation (including the core polarization) effects (see Refs. [2,18-20,30]).

Really, as it is indicated in Ref. [8], the semiempirical values agree with the ab initio SD calculations to better than 1% with the exceptions of the 7s-8p and 7s-9p transitions, where contributions from correlation corrections are very large. The most important conclusions relate to an effect of the gauge invariance on the transition amplitude values.

An estimate of the gauge-non-invariant contributions (the difference between the oscillator strengths values calculated with using the transition operator in the form of “length” G1 and “velocity” G2) is about 0.1%. The theoretical data, obtained with using the different photon propagator gauges (Coulomb and Babushkin ones) are practically equal.
